Abstract: Overactive bladder (OAB) is common in both men and women. It is a symptom complex that causes significant detriment to quality of life in patients. Although the prevalence of OAB is similar in both sexes, there are sex-specific differences in individual symptoms and the impact on quality of life. The coexistence of benign prostatic hyperplasia with OAB can worsen quality of life in men. This review examines the major studies that looked at the epidemiology of OAB as it relates to both sexes. It focuses on both the overall prevalence rates and the incidence of individual symptoms. This paper also addresses the level of bother and quality of life in men and women with OAB. In addition, the relationship between OAB and benign prostatic hyperplasia is reviewed.

Keywords: overactive bladder, prevalence, sex, LUTS, BPH, quality of life

Introduction

Overactive bladder (OAB) is a prevalent condition in both men and women. It may have a significant impact on overall quality of life, sexual function, sleep, and mental health. According to the International Continence Society (ICS) definition, OAB consists of urinary urgency with or without urge incontinence, often accompanied by frequency and nocturia. The urodynamic characteristic of OAB is detrusor overactivity (DO). Numerous publications have studied the prevalence of OAB in developed countries and assessed the impact it has on quality of life with various results.^{1,2} Although the overall prevalence of OAB is similar between the two sexes, there are sex-specific differences in the prevalence of various symptoms within the OAB complex.^{3,4} Anatomical and physiological differences in the lower urinary tract of males and females may help to explain these variations.⁴ Additionally, the underlying mechanisms that cause the outwardly similar symptomatology in men and women may be different. This review focuses on the epidemiology of OAB.⁵⁻⁹

EPIC study

This is one of the largest population-based surveys that studied the prevalence of lower urinary tract symptoms (LUTS) and OAB. Conducted in five countries, including Canada, Germany, Italy, Sweden, and the UK, the EPIC study was a cross-sectional telephone survey of adults aged >18 years.^{6,7} A computer-assisted telephone interview system was used, followed by a questionnaire that looked at patient-specific categories such as demographics and comorbidities. The study had >19,000 participants and

showed an overall OAB prevalence of 11.8%, with similar rates in men and women.⁶

This study used ICS definitions of LUTS and OAB to survey the prevalence of various symptoms in the population. The EPIC study showed that the prevalence of LUTS suggestive of OAB was 10.8% in men and 12.8% in women.⁶ It can be seen from the EPIC study that the incidence of LUTS in general was similar but slightly more common in women than in men (66.6% vs 62.5%).⁶ When divided into storage and voiding symptoms, sex differences are apparent. Storage symptoms were more common in women (59.2%) than in men (51.3%). On the other hand, voiding LUTS, such as intermittency, slow stream, and straining, were more common in men (25.7%) than in women (19.5%). The same was true for postmicturition symptoms such as postmicturition dribble or incomplete emptying, with prevalence being higher in men (16.9%) than in women (14.2%). Looking specifically at LUTS that define OAB, these were reported in 12.8% of women and 10.8% of men. This study opposes the commonly held misconception that OAB symptoms affect mostly older individuals. Approximately 73% of men and 72% of women who participated in the EPIC study were <60 years of age. Among the participants aged 40–59 years, 51% of men and 56% of women experienced storage symptoms. Among those aged <39 years, 38% of men and 49% of women experienced storage symptoms.⁶ However, it appears that the prevalence of OAB symptoms does increase with age in both sexes.

Urinary incontinence (UI) has also been studied extensively, and the prevalence rates vary widely. The EPIC study reported that women had a much higher rate of any UI (urge, mixed, stress, and other) than men (13.1% vs 5.4%).⁶ Stress urinary incontinence was the most common type in women, and other urinary incontinence (urge, mixed) was more common in men.

The EPIC study assessed the prevalence of frequency in the study population, which largely depends on the definition used. ICS defined frequency as the perception of urinating too often during the daytime.⁷ Using this definition, the EPIC study reports that 31% of men and 25% of women with OAB symptoms had frequency.⁷ Of these, 75% of men and 60% of women urinated eight or fewer times during the day, most of them falling within the five to eight voids per day range.⁷ When a different definition of frequency is applied, that is, voiding frequencies of greater than eight times per day, the prevalence of frequency decreases to 12% of men and 19% of women with OAB. Women with OAB and ICS defined frequency had a higher daytime voiding frequency than men

(8.2 vs 7 times per day). Women were more likely than men (19% vs 12%) to report frequency of more than eight times per day. Furthermore, women were more likely to be bothered by urinary frequency than men (66% vs 46%).⁷

The EPIC study used the ICS definition of nocturia as one or more voids per night. The EPIC study found that the general prevalence of nocturia was 48.6% in men and 54.5% in women. However, in those with OAB, the prevalence was 75% of men and 74% of women indicating that nocturia occurs commonly in this syndrome. If nocturia is defined as two or more voids per night, the prevalence decreases significantly in both sexes (20.9% of men and 24% of women).

The EPIC study confirmed that most patients with OAB had a combination of symptoms. Urgency with or without UI in the absence of frequency or nocturia was present in only 21% of men and 23% of women. Approximately 50% of OAB patients had a combination of two symptoms, and approximately one-third of patients reported a combination of three OAB symptoms.⁷ It was also rare to have patients who had all four symptoms (5% of men and 7% of women). Also rare was the incidence of frequency in the absence of nocturia, occurring in only 4% of both sexes with OAB (Table 1).⁷

NOBLE study

The National Overactive Bladder Evaluation (NOBLE) program was developed to estimate the prevalence of OAB and its burden in the United States.⁸ It also assessed the influence of sex on OAB and its symptoms. Furthermore, it focused on the impact of OAB on quality of life, sleep, and general mental health. It was conducted as a computer-assisted telephone interview followed by a self-administered questionnaire to assess quality of life. Out of >17,000 households that were contacted, 5,204 participants completed the interview.⁸ The study showed an overall OAB prevalence of ~16% with no significant differences between the two sexes (16% in men, 16.9% in women). The NOBLE study did not confirm the general belief that OAB and urgency symptoms are more common in women than men.

The NOBLE study revealed that specific OAB symptoms were more common in women than in men but with increasing age, especially over the age of 60 years, symptoms were predominant in men. Although the overall prevalence of OAB in men and women was similar, the incidence of OAB with and without urge incontinence showed significant sex variation. The NOBLE study demonstrated that in all age groups, OAB without UI was more common in men than in women. Urge incontinence increased with age in both

Table I Summary of key studies

	EPIC ^{6,7}	NOBLE ⁸	EpiLUTS ⁵	Milsom ⁹
Geography	Canada, Germany, Italy, Sweden, UK	USA	USA	France, Germany, Italy, Spain, Sweden, UK

Other	Frequency: female 25%, male 31%; nocturia: female 54.5%, male 48.6%	Prevalence of OAB with/without urge incontinence similar in women (9.3% vs 7.6%); prevalence of OAB with/without urge incontinence different in men (2.6% vs 13.4%)	Urgency and urge urinary incontinence: female 15.3%, male 9.3%	Frequency: 85%; urgency 54% (no difference between women and men); urge urinary incontinence: 36% (more prevalent in women)

Abbreviations: NOBLE, National Overactive Bladder Evaluation; EpiLUTS, epidemiology of lower urinary tract symptoms; OAB, overactive bladder.

sexes, increasing from 2% to 19% in women after the age of 44 years and from 0.3% to 9% in men with a marked increase after 64 years.⁸ The age-related increase in OAB with UI is much stronger in women than in men ($P<0.0001$). While there is a steady increase with age of OAB with UI in women throughout their lifetime, the main increase in the prevalence of OAB with UI in men only occurs after the age of 65 years. On the other hand, the prevalence of OAB without UI has a steeper age-related increase in men than in women ($P<0.0001$). This almost tripled in men from 8.5% in those <45 years of age to 21.8% in men after 55 years. In women, OAB without UI increased far more gradually and reached a plateau after the age of 44 years. Furthermore, while the prevalence of OAB with and without UI in women was similar (9.3% and 7.6%), in men the prevalence of OAB with UI (2.6%) was much lower than the prevalence of OAB without UI (13.4%).⁸

The NOBLE study also discovered an association between OAB with UI and body mass index (BMI) in women but not in men. Women with BMI >30 were 2.2 times more likely to have OAB with UI than women with BMI <24.⁸ Men who reported a history of prostate problems had a higher prevalence ratio of OAB with and without UI. Given that the overall prevalence of OAB is similar in men and women, the sex differences seen in UI suggest that there is a sex-specific cause for UI that could be attributed to the anatomical and physiological differences in urinary continence mechanisms

such as a shorter female urethra and the effect of pregnancy and vaginal delivery on the pelvic floor.⁸

EpiLUTS study

The epidemiology of lower urinary tract symptoms (EpiLUTS) survey was a population-based, cross-sectional survey conducted in the US, UK, and Sweden to evaluate the prevalence and bother of OAB and to update the results of the NOBLE survey done in 2003. Specific to the United States, 20,000 men and women aged >40 years were randomly selected from 1.5 million internet panel members.⁵ EpiLUTS examined the frequency of OAB symptoms segregated into categories and studied the level of bother in each category. The prevalence of OAB depended on how OAB was defined. When symptoms were defined as “sometimes”, the overall prevalence was 35.6%. When defined as “often”, the overall prevalence decreased to 24.7%.⁵ No matter how it was defined, the prevalence increased with increasing age.

Sex-specific differences were evident in the EpiLUTS study. In men, the prevalence rates of OAB symptoms “sometimes” and “often” were 27.2% and 15.8%, respectively, whereas in women, the prevalence rates of OAB symptoms “sometimes” and “often” were 43.1% and 32.6%, respectively.⁵ Women had an overall higher prevalence of symptoms such as urgency, UI, or both. All these symptoms increased in prevalence with increasing age in both sexes.

The EpiLUTS study examined symptom complexes in OAB. Isolated symptoms were rare in OAB. Urgency in isolation was present in 15.6% of men and 10.9% of women. Looking at urgency and urge incontinence as the only two OAB symptoms, this complex was reported in 9.3% of men and 15.3% of women.⁵ All four symptoms of OAB, including urgency, urge incontinence, frequency, and nocturia, were found in 16% of men and 20% of women.

Milsom study

Milsom et al⁹ conducted a population-based prevalence study to determine the prevalence and symptoms of OAB. The surveys were carried out in France, Germany, Italy, Spain, Sweden, and the UK. Telephone and direct interviews were conducted in 16,776 randomly selected men and women aged >40 years.⁹ The researchers used specific definitions of symptoms of OAB and stress incontinence and prostatic obstruction. The Milsom study found an overall prevalence of OAB symptoms of 16.6%.⁹ This study also examined the rate at which OAB patients sought medical advice and treatment.

Women were slightly more likely than men to report OAB symptoms with the sex-specific prevalence being 15.6% in men and 17.4% in women, even though other studies have suggested that male OAB was much more likely to have underlying DO than female OAB.¹⁰ The Milsom study looked at individual symptoms that occur in this condition, specifically frequency (85%), urgency (54%), and urge incontinence (36%), in order of most to least common.⁹ The overall prevalence of frequency and urgency was comparable irrespective of sex. However, urge incontinence was found to be more prevalent among women than men.⁹ It was found to be less common in both sexes to present with an isolated symptom (eg, frequency alone) or to present with all the symptoms of OAB. Most people presented with a varying mix of symptoms. The presence of all these symptoms increases with increasing age.

The prevalence of OAB symptoms in men increases slowly until the age of 70 years, but then a sharp increase can be observed after 75 years of age, with a slight fall in prevalence between the ages of 70 years and 75 years. In women, there is also a gradual increase seen until the age of 60 years, with a leveling off seen between 60 years and 70 years of age and a gradual increase in prevalence thereafter.⁹

Quality of life

Studies assessing quality of life highlight the significant negative impact that OAB has on daily activities, mental health, and sexual function.^{5-7,9,11,12} The Milsom study examined

the behaviors of individuals with OAB symptoms.⁹ Sixty-five percent of participants reported that OAB symptoms adversely affected their quality of life. Medical consultation rate was reasonably high in this study at 61%. However, less than one-third of patients who sought medical help were receiving medications. Furthermore, frequency and urgency symptoms were almost as much of a reason to seek help as was UI. Two-thirds of participants with OAB had tried a number of conservative measures such as decreasing fluid intake to manage their symptoms. The EpiLUTS study indicated that OAB symptoms are more bothersome for women than men.⁵ This differs from the EPIC study where almost identical levels of bother were reported by women (53%) and men (54%) who suffered OAB.^{6,7} Women were twice as likely as men to use various coping strategies such as physiotherapy and absorbent products as nonmedical management of OAB.⁹ The EpiLUTS study suggests that the motivation to seek medical help is related to the number of symptoms, the level of bother, and the age of the patient.⁵ It appears that older patients are more likely to consult a doctor than younger patients with OAB. One of the main reasons for not seeking help or advice was the lack of awareness that effective treatment was available for such conditions.

The review of Irwin et al of the EPIC study showed that the degree of bother among OAB sufferers increased as the number of LUTS increased.⁷ Twelve different LUTS were assessed by the EPIC study. In those suffering only urgency, 14% of men and 8% of women were bothered by their symptoms. In those who reported urgency and one other LUTS, 28% of men and 33% of women experienced reportable bother. The prevalence of bother increased significantly in those who reported urgency with two other LUTS. This indicates that urgency alone is not as bothersome to most OAB patients, and it is the addition of further LUTS that dramatically impacts on the level of bother and quality of life. The EpiLUTS study confirmed the findings of the EPIC study that the likelihood of bother increased with the number of OAB symptoms present with 100% of men and 90% of women with all four OAB symptoms reporting that they were bothered at least "somewhat".⁵

The effect of nocturia on quality of life is significant. It is controversial if one episode of nocturia per night is significant, since many experts believe this falls within the normal clinical spectrum.⁷ However, in the EPIC study, among OAB sufferers, 19% of men and 24% of women with one episode of nocturia per night were bothered by it. The prevalence increases dramatically when sufferers experience two or

Table 2 Bother level in key studies

EPIC ^{6,7}	OAB symptoms have similar bother in women (53%) and men (54%)	The degree of bother increased as the number of LUTS increased
NOBLE ⁸	No data	No data
EpiLUTS ⁵	OAB symptoms more bothersome in women (67.6%) than in men (60%)	Motivation to seek medical help was related to the number of symptoms, level of bother, and age of patient
Milsom ⁹	Quality of life affected in 65% of patients with OAB: women 67%, men 65%	Less than one-third of patients who sought medical help were currently receiving medications

Abbreviations: NOBLE, National Overactive Bladder Evaluation; EpiLUTS, epidemiology of lower urinary tract symptoms; OAB, overactive bladder.

more episodes of nocturia. Studies have shown that even in healthy individuals, any episodes of nocturia can have a significantly negative impact on quality of life, sleep, work performance, and general well-being.⁷ This impact is greater in those who suffer from multisymptom OAB (Table 2).

Coexistence of OAB with benign prostatic hyperplasia

There is presumed to be an association between OAB and bladder outlet obstruction (BOO) secondary to benign prostatic hyperplasia (BPH) with several studies recognizing them as common comorbid conditions.¹³ Up to 50% of men with BOO are estimated to have OAB symptoms.^{14,15} Some studies have noted that 50% of men with LUTS and urodynamically confirmed BOO have DO.¹⁶ OAB symptoms may develop secondary to BOO.¹⁷ In these men, treatment can be challenging as there is theoretical concern that anticholinergic treatment may precipitate urinary retention. On the other hand, studies have estimated that 40% of men with BOO and OAB continue to have overactivity symptoms despite treatment and relief of BOO.^{14,17} Abrams et al¹⁸ proposed some of the mechanisms by which BOO leads to DO, which include denervation from ischemia, physiological changes in the bladder wall, and neural control of bladder contraction induced by BOO. Early explanations include “increased irritability” of the bladder associated with BOO.¹⁹ The prevalence of BOO increases with age. Therefore, it is more likely for older men with symptomatic OAB to have underlying BOO as a potential cause for their symptoms. Men younger than 50 years of age with OAB symptoms are less likely to have significant BOO.¹⁵ De Nunzio et al studied the evolution of bladder overactivity in men with BOO. They examined 255 patients with symptomatic BOO who were stratified according to the treatment they received including medical therapy, surgical therapy, and

watchful waiting.¹⁹ They underwent urodynamic testing both at baseline and at a mean of 2 years of follow-up. In general, DO was highly prevalent in patients with BOO. Overall, 52% and 40% of patients with BOO demonstrated DO at baseline and follow-up, respectively. When stratified according to the treatments received, these figures were 45% and 55% in the watchful waiting group, 35% and 30% in the alfuzosin group, 46% and 30% in the transurethral incision group, and 68% and 31% in the prostatectomy group.¹⁹ This suggests that various treatments for BOO can have an impact on DO over time with decreased incidence of DO in these patients. Lee et al¹⁴ studied 144 patients with LUTS in a prospective analysis. Urodynamic studies were performed to look for DO. Of these, 47% of patients had BOO and OAB. Only 35% of patients with coexisting BOO and OAB reported symptomatic improvement after taking doxazosin monotherapy for 3 months. Of the remaining 65% who did not respond, 73% had a symptomatic improvement after the addition of tolterodine.¹⁴ Of the 16 patients with BOO only, who did not respond to doxazosin monotherapy, six patients reported symptomatic improvement after the addition of tolterodine. The current literature supports the use of combination therapy with anticholinergic agents and alpha blockers.¹⁷ Studies evaluating anticholinergic and beta 3 agonist (mirabegron) therapies have shown that both can be safely administered in men with BOO and OAB without negative effects on voiding or urodynamic pressures.¹³ It has also been demonstrated that fesoterodine in flexible doses (4 mg or 8 mg) in men with persistent OAB symptoms is well tolerated.¹⁵

Neurogenic versus nonneurogenic OAB

In this review, we did not differentiate between neurogenic and nonneurogenic OAB. The studies that we examined in this review did not specifically include or exclude neurogenic bladder, and we believe this review represents OAB in the general population. In general, the studies excluded participants who were pregnant or had active urinary tract infections.^{5,8,9} The NOBLE and Milsom studies specified the definition of OAB as being urinary urgency with or without urge incontinence, in the absence of pathologic or metabolic factors that would otherwise explain the symptoms.^{8,9} The NOBLE study sought information regarding medical conditions such as diabetes, heart failure, multiple sclerosis, Parkinson’s disease, spinal cord injury, cancer, and interstitial cystitis.⁸ This review excluded secondary causes of OAB symptoms including diabetes, heart failure, cancer, bladder surgery, previously diagnosed prostate enlargement, interstitial cystitis, pregnancy, recent birth, medications, and excessive fluid intake. This made

47% of participants who completed the survey ineligible.⁸ The Milsom study included patients with or without a possible neurological cause for their symptoms.⁹ Their exclusion criteria included urinary tract infections, pure stress incontinence, and symptoms suggestive of prostatic obstruction.

Summary

Multiple studies have assessed the prevalence of OAB and the impact it has on quality of life. We have presented here the significant findings of a number of studies conducted in this area. The information presented in these studies is often contradictory and confusing. However, there were some common threads. OAB is common in both women and men. The prevalence of OAB and its symptoms increases with increasing age in both sexes. While the overall prevalence is similar in both sexes, there are some sex-specific differences. Urge incontinence is more common in women than in men. Isolated symptoms are rare in OAB. It is much more common to have a combination of symptoms in both sexes with frequency being the most commonly reported symptom. OAB in both sexes has a significant impact on the quality of life, quality of sleep, and mental health. Furthermore, the level of bother increases with the number of symptoms experienced. BPH and BOO commonly coexist with OAB and worsen the level of bother and quality of life in men. Assessment of LUTS in men should take this into account, and treatment should be tailored to address both.
